FSMNLP 2008

1 Introduction

2 Model

3 Evaluation

4 Comments

Scenario

- Synchronic and diachronic study of language change and acquisition models
  - Language data from a long period of time, and three major dialects in Croatia implying:
    - Variation wrt. e.g. string-based morphology or feature bundles
    - Ongoing discovery wrt. string combinatorics and features

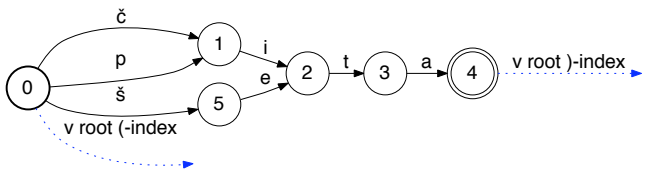
- Research questions require quantitative and qualitative information:
  - of phonological, morphological, syntactic and semantic tokens and feature bundles, and their correlation and variation at various stages over time

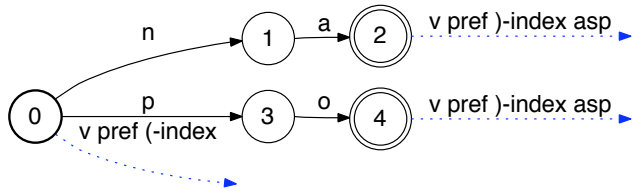
Morphological segmentation and annotation
and lemmatization, and . . .

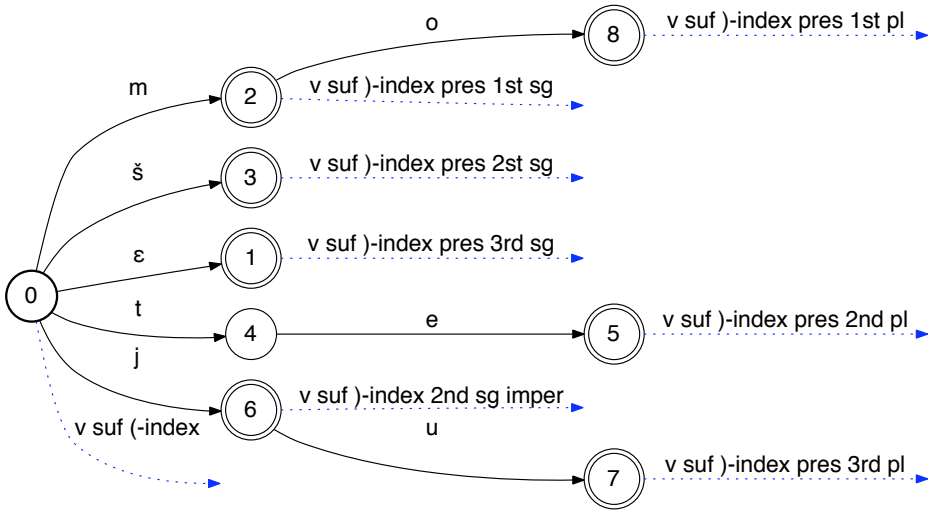
- Segmenting words:
  - *isponapijali su se* "they got drunk a little bit to satisfaction"
  - *is – po – napija – li*
- Annotating segments:
  - aspect prefix – aspect prefix – from stem-lemma *napiti* – plural participle
- Extending the annotation:
  - to a certain saturation – a little bit – "get drunk" from root-lemma *piti* – past event

FSA Architecture

Mapping of morph-groups to DFSAs (Mealy or Moore machine):







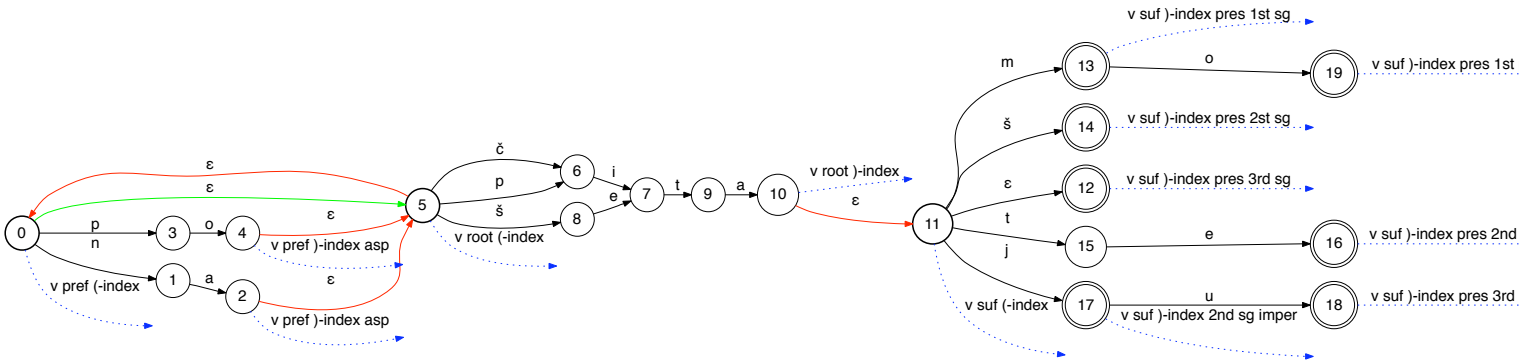
FSA Architecture

- Mapping ambiguity on emission: emission tuple 1 to *n*
- Label DFSAs with variable names
- Use rules referring to variable names for modeling of morphotactic regularities:

```
verbAspectPrefs* . verbAtiRoots . verbInflSuf
```

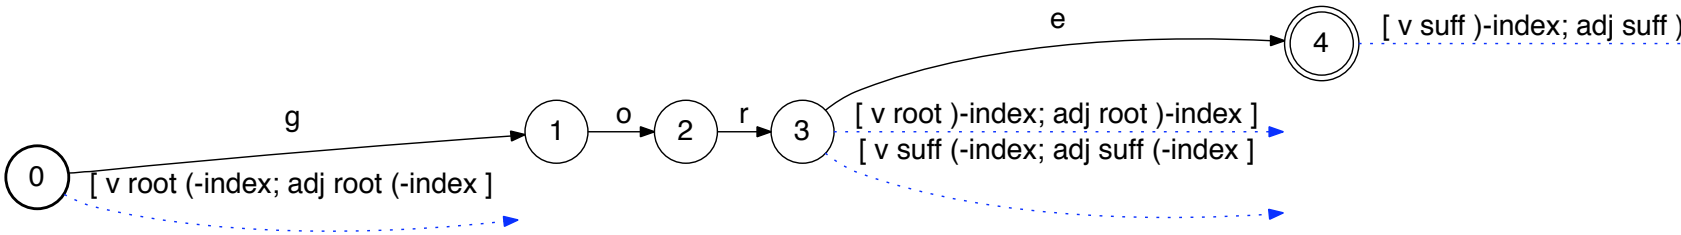
FSA Architecture

Generating potentially cyclic DFSAs:



FSA Architecture

Ambiguity mapped on emission tuple:



FSA Architecture

Lemmatization as a rule:

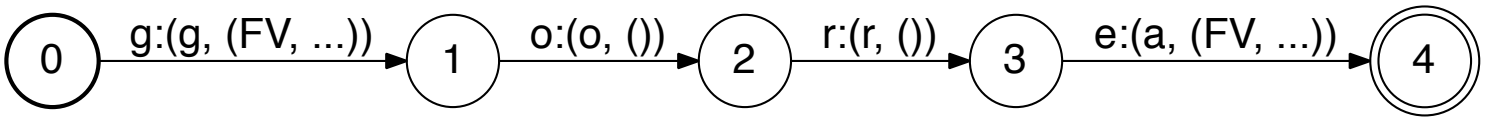
- Rightmost root is the semantic head
- Root-lemma: generate canonical word-form from the right-most root
  neprijatelja $\rightarrow$ *ne* + *prijatelj* + *a* $\rightarrow$ *NEG* + *N-root* + *ACC*
  "not friend" = "enemy" $\not\Rightarrow$ $\neg$friend not compositional!
  but useful for semantic field analysis!
  root-lemma: *neprijatelja* $\rightarrow$ *prijatelj*
- Stem/base-lemma: generate canonical word-form from the stem without inflectional suffixes
  base-lemma: *neprijatelja* $\rightarrow$ *neprijatelj*

FSA Architecture

Lemmatization (Hack):

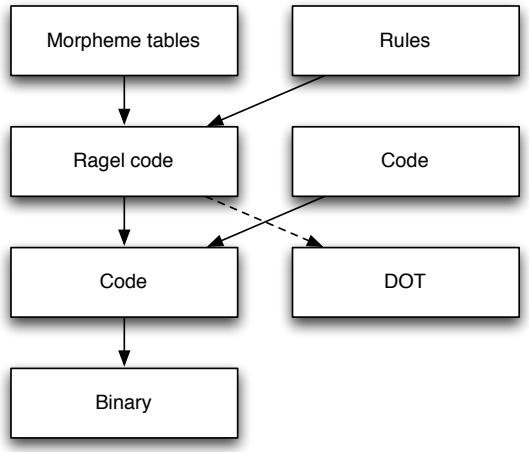
- emission of byte-offset for suffix-elimination
- pointer to suffix string

Clean solution:



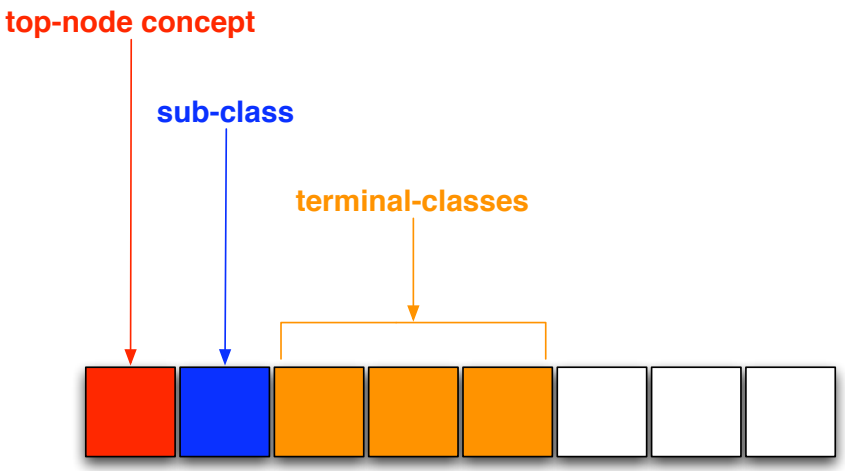
Implementation

- C++ wrapper for final application
- Ragel code (automaton definition) generated from morpheme DBs and rules, with associated feature bundles (extended version of Ragel, ($\geq$ V. 6.1) for handling ambiguity via introduction of multiple emission symbols = emission tuples)
- Ragel generated C code (jump-code)



Implementation

- Emission (feature bundles): as one bit-vector
- Features mapped from the General Ontology for Linguistic Description (upper ontology)
  - possibility: reasoning over linguistic concepts and features
- Optimization: mapping of concepts and their relations on a compressed bit-vector, maintaining inheritance and implicatures



Evaluation

- Hardware: dual core 2.4 GHz
- Lexical base: 120,000 morphemes (and allomorphs)
- Speed: approx. 50,000 tokens per second with average morpheme count of 2.5 per token
- Size: binary footprint approx. 5 MB
- Compilation (tables $\rightarrow$ Ragel + C; Ragel $\rightarrow$ C + DOT; gcc $\rightarrow$ bin): approx. 5 minutes, min. 4 GB RAM for monolithic architecture

Comments

- Interoperability issues addressed:
  - GOLD
  - platform independent code
  - code-page independence
- Extensible (turnaround time of some minutes)
- Minimally invasive and minimalistic
- Open-source
